# Abstract

In this work, we describe and use Optimal Matching — a method widely used in sociological studies — to obtain pairwise distances between categorical sequences that represent the relationship and family history of a group of women over 40 years old. We then use the distances to predict five personality traits. For prediction, we apply  $k$ -nearest neighbors ( $k$ -NN) and compare the performance of different approaches for the calculation of the cost matrix, normalization and handling of missing values in the sequences. We find that the quality of the prediction varies across several considerations resulting in a different scenario for the best prediction of each trait.

# Introduction

Optimal matching (OM) is an adaptation of the Needleman-Wunsch algorithm (Needleman & Wunsch (1970)) and since its introduction in social sciences by Abbott & Forrest (1986), it has been extensively used to answer questions involving processes that take values in a categorical set of states and occur along a specific period of time. For instance, in sociology, optimal matching has been employed in several studies tracking the professional development of specific groups of people, see Chan (1995), Biemann & Datta (2014) or Gubler, Biemann, Tschopp, & Grote (2015), and to analyze life course data, for example, Widmer & Ritschard (2009) or Bastin (2015).

The common result of several studies employing optimal matching is to find similarities and dissimilarities among categorical sequences and identify groups of trajectories that exhibit similar patterns. This is achieved through the application of clustering techniques to the distance matrix generated with help of the algorithm.

However, critics as Wu (2000) point out that optimal matching has limitations. A notable flaw lies in the definition of the cost matrix and the strong assumption about its symmetry.

In this work, we use a dataset that contains categorical sequences of the relationship history of a group of women in the context of the ‘Women 40+ Healthy Aging Study’. We explore the potential to obtain predictions of additional variables, namely personality scores, based on the information obtained from the sequential data via optimal matching. For this purpose, we use the implementation of the algorithm in the R package **TraMineR** (Gabadinho, Ritschard, Müller, & Studer (2011)) and the visualizations provided by **TraMineRextras**.

In Section 1, we provide a detailed description of the optimal matching algorithm, the methods considered to obtain the cost matrix and the normalization methods for the distance matrix. In Section 2, we introduce the data used in this work and perform optimal matching to obtain clusters of sequences and use visualizations to provide a description of the groups. In Section 3, we describe  $k$ -nearest neighbors

---

( $k$ -NN), the method we chose for prediction of the personality scores based on the data from the previous section. In Section 4, we show some of the additional scenarios considered, specifically those that produce the best predictions for each personality trait. Finally, we present some conclusions and recommendations for future work.

# Section 1

## Optimal Matching

Optimal Matching is a technique widely applied in social sciences for the comparison of sequences that take values in a finite set of categories or states and are indexed by time. For instance, in sociology, OM has been used for life course or career path analysis.

OM uses the Needleman-Wunsch algorithm, developed by Needleman & Wunsch (1970) to identify similarities between sequences (for instance, DNA or protein sequences) that are usually represented as strings of characters. This algorithm is an application of dynamic programming, an iterative method that simplifies an optimization problem by breaking it into a recursion of smaller problems that are simpler to solve. By choosing the optimal operation at each step, it is guaranteed that the overall solution is optimal as well.

The goal of OM is to find the best possible alignment between two sequences by considering the differences and equivalences between their elements and minimizing the total cost associated. The cost of changing between states of the sequences we are interested in aligning, can be defined in several ways including data-based methods or values supplied by experts in the particular field.

### 1.1 The OM algorithm

Consider a set of  $n$  categorical states  $S = \{s_1, \dots, s_n\}$ , we define  $X = (x_1, \dots, x_t)$ , a sequence of length  $t < \infty$ , where  $x_i \in S$  for  $i = 1, \dots, t$ . Further, let  $\mathbf{S}$  be the set of all possible sequences with states belonging to  $S$ .

Now, let  $X, Y \in \mathbf{S}$  be two sequences of size  $t_X$  and  $t_Y$ , respectively. In order to numerically assess the dissimilarity between the sequences  $X$  and  $Y$ , we define an empty array  $F$  of size  $(t_X + 1) \times (t_Y + 1)$ . Algorithm 1 below shows the initialization

and recursion to fill the array  $F$ .

---

**Algorithm 1** Optimal matching.

---

```

1:  $F(1, 1) \leftarrow 0$ 
2: for  $j \leftarrow 2, t_Y + 1$  do
3:    $F(1, j) \leftarrow F(1, j - 1) + d$ 
4: end for
5: for  $i \leftarrow 2, t_X + 1$  do
6:    $F(i, 1) \leftarrow F(i - 1, 1) + d$ 
7: end for
8: for  $i \leftarrow 2, t_X + 1$  do
9:   for  $j \leftarrow 2, t_Y + 1$  do
10:     $F(i, j) \leftarrow \min\{F(i - 1, j) + d, F(i, j - 1) + d, F(i - 1, j - 1) + K(y_{i-1}, x_{j-1})\}$ 
11:   end for
12: end for

```

---

The value  $d$  is the cost of inserting a gap in one of the sequences, also known as *indel* cost, and  $K(y_{i-1}, x_{j-1})$  is the cost associated to change from the state  $y_{i-1}$  to  $x_{j-1}$ , which is defined in a matrix  $K$  of size  $n \times n$ , commonly known as the cost matrix.

Lines 1-7 of the OM algorithm correspond to initialization. Starting with a cost of 0 in  $F(1, 1)$ , the first row and column of  $F$  represent cumulative costs of successively adding gaps. The remaining lines of the algorithm correspond to the row-wise recursion to fill the array  $F$  according to the content of the sequences to be compared: at any step of the recursion, the algorithm is looking at a specific pair of indexes (location) and calculating if substitution or insertion/deletion is the cheapest operation. Successively adding the costs of the cheapest operations results in the overall optimal cost for aligning the sequences  $X$  and  $Y$ .

In fact, when  $F$  is completely filled, the value in the last cell, i.e.  $F(t_X + 1, t_Y + 1)$  corresponds to the optimal cost of aligning the sequences  $X$  and  $Y$ . It is possible to recover the steps that conduced to this alignment with a traceback from the last cell. However, this is not necessary to obtain the dissimilarities matrix for a set of sequences.

The R packages **TraMineR** (Gabadinho et al. (2011)) and **TraMineRextras** provide several functions to define, analyze and visualize sequential data. In particular, **TraMineR** implements the OM algorithm and offers several methods for computing the cost matrix  $K$  and the normalization of the dissimilarity matrix.

## 1.2 Cost matrix

The cost matrix  $K$  is a symmetric matrix of size  $n \times n$ . The value in the  $i$ -th row and  $j$ -th column  $K(s_i, s_j)$  indicates the cost of moving from state  $s_i$  in time  $t > 0$  to state  $s_j$  in  $t + 1$ .

The following are the methods available in **TraMineR** to obtain the cost matrix.

### 1.2.1 Transition rates (TRATE):

The substitution cost between states  $s_i$  and  $s_j$ ,  $1 \leq i, j \leq n$ , is calculated as:

$$K(s_i, s_j) = c - P(s_i|s_j) - P(s_j|s_i), \quad (1.1)$$

where  $P(s_i|s_j)$  is the probability of transition from state  $s_j$  in time  $t$  to  $s_i$  in time  $t + 1$  and  $c$  is a constant, set to a value such that  $0 \leq K(s_i, s_j) \leq 2$ .

### 1.2.2 Chi-squared distance (FUTURE):

$$K(s_i, s_j) = d_{\chi^2}(\mathbf{P}_i, \mathbf{P}_j), \quad (1.2)$$

where  $\mathbf{P}_. = (P(s_1|s.), \dots, P(s_n|s.))'$

### 1.2.3 Relative frequencies (INDELS and INDELSLOG):

$$K(s_i, s_j) = d_i + d_j, \quad (1.3)$$

where the *indel* cost  $d_i$  depends on the state and takes values:

$$g_i = \frac{1}{f_i}, \quad \text{for method 'INDEL',} \quad (1.4)$$

$$g_i = \log \left( \frac{2}{1 + f_i} \right), \quad \text{for method 'INDELSLOG',} \quad (1.5)$$

and  $f_i$  is the relative frequency of the state  $s_i$  for  $i = 1, \dots, n$ .

#### Remarks:

- For methods **TRATE** and **FUTURE**, the unique *indel* value is  $d = \max_{1 \leq i, j \leq n} K(i, j)/2$ , so that the cost of any change of state is always lower or equal than deleting and inserting an element (or vice versa).

- The Needleman-Wunsch algorithm with constant costs for mismatch is known as Levenshtein distance (Levenshtein (1966)), a string metric widely used in computer science.
- In general, the resulting measure of the algorithm is a dissimilarity. However, if the cost matrix fulfills the triangle inequality, we obtain a distance measure.

### 1.2.4 Example

Suppose that  $S$  is the alphabet and let  $X = \{S, E, N, D\}$  and  $Y = \{A, N, D\}$  be two sequences in  $\mathbf{S}$ .

Further let  $d = 2$ , and

$$K(i, j) = \begin{cases} 0 & \text{if } i = j, \\ 3 & \text{otherwise} \end{cases}$$

The array  $F$  is initialized as follows:

	S	E	N	D
0	2	4	6	8
A	2			
N	4			
D	6			

Then, to fill the second row of  $F$  we proceed as follows:

$$\begin{aligned}
 F(2, 2) &= \min\{F(1, 2) + d, F(2, 1) + d, F(1, 1) + k(y_1, x_1)\} \\
 &= \min\{2 + 2, 2 + 2, 0 + 3\} \\
 &= 3 \\
 F(2, 3) &= \min\{F(1, 3) + d, F(2, 2) + d, F(1, 2) + k(y_1, x_2)\} \\
 &= \min\{4 + 2, 3 + 2, 2 + 3\} \\
 &= 5 \\
 F(2, 4) &= \min\{F(1, 4) + d, F(2, 3) + d, F(1, 3) + k(y_1, x_3)\} \\
 &= \min\{6 + 2, 5 + 2, 4 + 3\} \\
 &= 7 \\
 F(2, 5) &= \min\{F(1, 5) + d, F(2, 4) + d, F(1, 4) + k(y_1, x_4)\} \\
 &= \min\{8 + 2, 7 + 2, 6 + 3\} \\
 &= 9
 \end{aligned}$$

What yields:

	S	E	N	D	
	0	2	4	6	8
A	2	3	5	7	9
N	4				
D	6				

Finally, after completing the recursion for the remaining rows, we obtain the following  $F$  array:

	S	E	N	D	
	0	2	4	6	8
A	2	3	5	7	9
N	4	5	6	5	7
D	6	7	8	7	5

In this simple example, we can easily obtain two optimal (equivalent) alignments without using the algorithm:

S E N D with

A – N D or  
 – A N D

In both cases we have two matches (cost 0), one mismatch (cost 3) and one gap (cost 2), giving a total cost 5 that is exactly what we obtained in the last cell of  $F$ .

The cost of inserting a gap ( $d$ ) is also known as *indel* (insert or delete) cost. In this example we can observe that, in order to obtain sequence  $X$  from  $Y$  we have to **insert** a term (i.e. insert a gap and then change its value to a specific state). Equivalently, to obtain sequence  $Y$  starting from  $X$  we have to **delete** one term.

## 1.3 Normalization

In cases when the lengths of the sequences differ, it can be useful to account for this differences with a normalization factor.

Given a set two sequences  $X, Y \in \mathbf{S}$  of length  $t_X$  and  $t_Y$ , respectively. Let  $d(X, Y)$  be the distance between the sequences  $X$  and  $Y$ ,  $t_{max}$  the length of the longest sequence in  $\mathbf{S}$  and  $d_{max}$  the maximum distance between any pair of sequences in  $\mathbf{S}$ .

TraMineR offers the following options to normalize the distances between sequences:

- `maxlength:`

$$\frac{d(X, Y)}{t_{max}}$$

- `gmean:`

$$1 - \frac{d_{max} - d(X, Y)}{\sqrt{t_X * t_Y}}$$

- `maxdist:`

$$\frac{d(X, Y)}{d_{max}}$$

## Section 2

# Data from the 40+ Healthy Aging Study

### 2.1 About the data

As part of the Women 40+ Healthy Aging Study, a large study that was conducted by the Department of Clinical Psychology and Psychotherapy of the University of Zurich, a psychometric instrument was developed in order to obtain information about the history of romantic relationships of women. The study was conducted between June 2017 and February 2018 with women between 40 and 75 years who (self-)reported good, very good or excellent health condition and the absence of acute or chronic somatic disease or mental disorder. The participants who reported psychotherapy or psychopharmacological treatment in the previous 6 months, as well as habitual drinkers, were excluded. Other exclusion criteria were pregnancy in the last 6 months, premature menopause, surgical menopause, intake of hormonal treatment (including contraceptives), shift-work and recent long-distance flight. The participants were recruited from the general population using online advertisement and flyers.

The questionnaire asked the participants to provide information about relationship phases starting from the age of 15 years until the current age at the time of the data collection. The phases were defined by the start and end age and for each phase and information about civil status, relationship status, living situation, children and quality of the relationship was collected. Before including the data corresponding to their own history, the participants were prompted to answer some of the questions based on an example. Some of the participants were excluded when the example entries were not correctly filled. After data cleaning and revisions for consistency the

total number of individuals considered in this work is 239.

In order to create a sequence for each participant the information about civil status, relationship status, living situation and the maternity is taken into account. A yearly sequence is created and the states considered are the following:

- 1 = Single + no children
- 2 = Single + children
- 3 = Changing relationships + no children
- 4 = Changing rel. + children
- 5 = Relationship + living apart + no children
- 6 = Relationship + living together + no children
- 7 = Relationship + living apart + children
- 8 = Relationship + living together + children
- 9 = Married + no children
- 10 = Married + children

Additionally, personality scores for the women included in the study are available. Personality refers to the enduring characteristics and behavior that comprise the unique adjustment to life of a person, including major traits, interests, drives, values, self-concept, abilities, and emotional patterns. These scores are obtained via psychometric instruments and evaluate the main personality traits:

- Agreeableness
- Conscientiousness
- Extraversion
- Neuroticism
- Openness

## 2.2 OM Application

Using the R package `TraMineR` the cost matrix is calculated with transition rates between states. We consider a base setup with method `TRATE` for the calculation of the cost matrix and `maxlength` normalization for the dissimilarities matrix. The cost matrix obtained this way is shown in table 2.1. As expected, the elements in the diagonal are equal to 0, meaning there is no cost associated to staying in the same state. By default, the constant  $c$  in 1.1 is set to 2. This, and the fact that the duration of the states is often longer than the time unit (one year), makes that all of the values outside the diagonal are close to 2 and even equal in cases where

Table 2.1: Cost matrix obtained from transition probabilities.

State	1	2	3	4	5	6	7	8	9	10	NA
1	0.00	2.00	1.98	2.00	1.92	1.95	2.00	1.99	1.98	1.98	2
2	2.00	0.00	2.00	2.00	2.00	2.00	1.96	1.92	2.00	2.00	2

6	1.95	2.00	1.92	2.00	1.95	0.00	2.00	2.00	1.98	1.96	2
7	2.00	1.96	2.00	1.95	1.98	2.00	0.00	1.97	2.00	2.00	2
8	1.99	1.92	2.00	1.95	1.99	2.00	1.97	0.00	2.00	1.98	2
9	1.98	2.00	1.97	2.00	1.98	1.98	2.00	2.00	0.00	1.99	2
10	1.98	2.00	1.98	2.00	1.97	1.96	2.00	1.98	1.99	0.00	2
NA	2.00	2.00	2.00	2.00	2.00	2.00	2.00	2.00	2.00	2.00	0

no transition between the states were observed in the data (e.g. from single without children to single with children and vice versa). Finally, we observe that missing value (NA) is considered as a separate state and, by default, the cost of changing from or to a missing value is 2, which might be too high in cases where the individuals made a mistake in the beginning or end age of a phase leaving a gap in the sequence.

From this cost matrix it is possible to calculate pairwise distances between all the sequences using the optimal matching algorithm as described in the previous section. As stated before, a correction of the distances is done to account for the differences in size of the sequences. This is done dividing the obtained distance by the length of the longest sequence.

Having obtained the distance matrix, we apply a hierarchical agglomerative clustering method in order to explore the data and the differences captured by the distance matrix. In particular, we set the number of clusters to 4. Figure 2.2 shows the distribution of the states for each of the identified clusters.

In figure 2.3 we show the transverse entropy by cluster, i.e. the cross-sectional entropy of the states distributions is calculated at each time point as follows:

$$h(f_1, \dots, f_n) = - \sum_{i=1}^n f_i \log(f_i). \quad (2.1)$$

These visualizations allow us to identify common and contrasting features of the clusters that can be useful to describe them concisely. In table 2.4 we present a summary of the clusters with our descriptive interpretation of the clusters. It is important to remember that this descriptions are subjective and not exhaustive.

On the other hand, in figure 2.2 we can also appreciate that the conformation

Figure 2.2: Distribution of states by cluster.

of some clusters seems to be highly affected by the length of the sequence and it is reasonable to assume that the normalization method is not achieving the ideal result.

Now, we are interested in exploring how the relationships history of the women relate to personality traits. As a first exploratory step, figure 2.5 shows the distribution of the score for each trait by cluster. No difference is obvious at first glance. Also, the number of clusters and the fact that the personality scores are not continuous makes it difficult to identify differences. For that reason, we also explore with a lower number of clusters.

By setting the number of groups to only two, we obtain better defined clusters that are less affected by the length of the sequences as we can observe in the distribution plots of the sequences states (figure 2.6): the majority of women in cluster 1 have children, while we mostly find women without children in cluster 2. In addition, the transversal entropy of the sequences for the two clusters is displayed in figure 2.7, where it is shown that the entropy decreases significantly around mid age for the cluster of women with children as compared to women without children, which means that the variability of the states for the first group is much lower as compared to the second group. This can be interpreted as a sign of stability in the relationship status for women during the time they have children at home.

Figure 2.3: Transversal entropy by cluster.

Table 2.4: Initial cluster summary.

Cluster	n	Share	Description
1	96	40.2%	Married young and had children.
2	37	15.5%	Often in relationships but not married.
3	73	30.5%	Older, mostly married or in long relationship without children.
4	33	13.8%	Younger, single or in a relationship without children.

As before, we want to explore possible links between the information from the sequences and personality scores. Figure 2.5 shows the distribution of the personality traits for the two clusters.

There seems to be differences in the distributions of some personality scores: the scores of agreeableness are concentrated in larger values for women with children; women without children have greater frequency in lower values of conscientiousness than women with children; and women with children exhibit lower scores of neuroticism.

Even though, the distribution of personality scores by cluster does not reveal clearly significant differences, having a distance matrix provides us a numerical expression of the categorical sequences that is useful for other purposes. In particular, we explore the predictive capability of this data with a non-parametric prediction method in the next section.

## Section 3

# Personality Scores Prediction with k-Nearest Neighbors

Given a training set  $\mathcal{D} = (x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)$  of  $n$  labeled data points, where  $x_i \in \mathbb{R}^d$  and  $y_i \in \mathcal{Y}$ , a finite set of class labels for classification or a continuous range of values for regression,  $k$ -NN provides a way to predict the label or value for a new, data point  $x_{n+1}$  (for which  $y_{n+1}$  is unknown) by finding the  $k$  training data points closest to  $x_{n+1}$  and taking a majority vote of their labels (for classification) or averaging the values of  $Y$  (for regression). That is, for a given distance function or norm  $d(\cdot, \cdot)$  we predict  $y_{n+1}$  as:

$$\hat{y}_{n+1} = \frac{1}{k} \sum_{j=1}^k y_{(j)} \quad (3.1)$$

where  $j = (1), \dots, (k)$  index the nearest  $k$  neighbors of  $x_{n+1}$ :

$$d(x_{(1)}, x_{n+1}) < \dots < d(x_{(k)}, x_{n+1}) < d(x_{(k+1)}, x_{n+1}) < \dots < d(x_{(n)}, x_{n+1}) \quad (3.2)$$

There are different choices for the distance function  $d(\cdot, \cdot)$ . For instance, the Euclidean or Mahalanobis distances are common choices. In our case we already count with a matrix distance obtained with OM. Note that in this setup,  $d(\cdot, \cdot)$  is one of the multiple normalized distances  $d(\cdot, \cdot) = d'(\cdot, \cdot | K)$  and it is dependent or parametrized by the cost matrix  $K$ .

$k$  is also a hyperparameter that can be tuned to optimize the performance of the  $k$ -NN algorithm. A larger  $k$  reduces the effect of noise and outliers but can also lead to overfitting. A smaller  $k$  is more sensitive to noise and outliers but can capture better the local structure.

To compare the performance of different values of  $k$ , we use the mean squared error (MSE). For a testing set of  $m$  labeled data points, the MSE is given by:

$$\text{MSE} = \frac{1}{m} \sum_{i=1}^n (Y_i - \hat{Y}_i)^2 \quad (3.3)$$

where  $y_i$  is the observed value and  $\hat{Y}_i$  is the predicted value via  $k$ NN.

In this part of the analysis we only consider the individuals who have available personality scores, that leaves us with a sample size of 200 individuals. We also split the data into two subsets: train (70%) and test (30%) and we evaluate the MSE of the predictions for the individuals in the test set only using the data from the nearest neighbors available in the train set.

For each trait  $Y$ , we predict the values and compare them with the observed values using the MSE. Table 3.1 summarizes the results of the optimal prediction and figure 3.2 shows the MSE for the different values of  $k$ , i.e. for  $k = 1, \dots, 80$ . As a reference, a red line for every personality trait is added to indicate the MSE of the trivial prediction, i.e. the mean of all the sample points in the train set. Recall that we are using the cost matrix  $K$  shown in 2.1 and normalized distance defined by the `maxlength` method as described in section 2.2.

Table 3.1:  $k$ -nn prediction summary.

Trait	$\min(\text{MSE})$	k	Trivial MSE
Agreeableness	0.59	48	0.62
Conscientiousness	0.37	15	0.40
Extraversion	0.71	22	0.76
Neuroticism	0.64	7	0.71
Openness	0.54	12	0.54

Overall, it seems that using the sequential data for prediction results in little improvement compared to the trivial prediction except for neuroticism.

Furthermore, for conscientiousness and openness, the MSE does not seem to increase again as  $k$  increases, which is expected when using  $k$ NN, due to overfitting. Moreover, for openness, the prediction with  $k$ NN is always worse than the trivial prediction. For conscientiousness, the MSE takes a minimum value for  $k = 15$  and after  $k = 30$  the MSE curve stays flat.

For agreeableness, the MSE increases again after the optimal  $k$ . However, note that this minimum is not considerably lower than the trivial prediction. Similarly, for extraversion, the MSE takes a minimum value with  $k = 22$ , but is not a significant

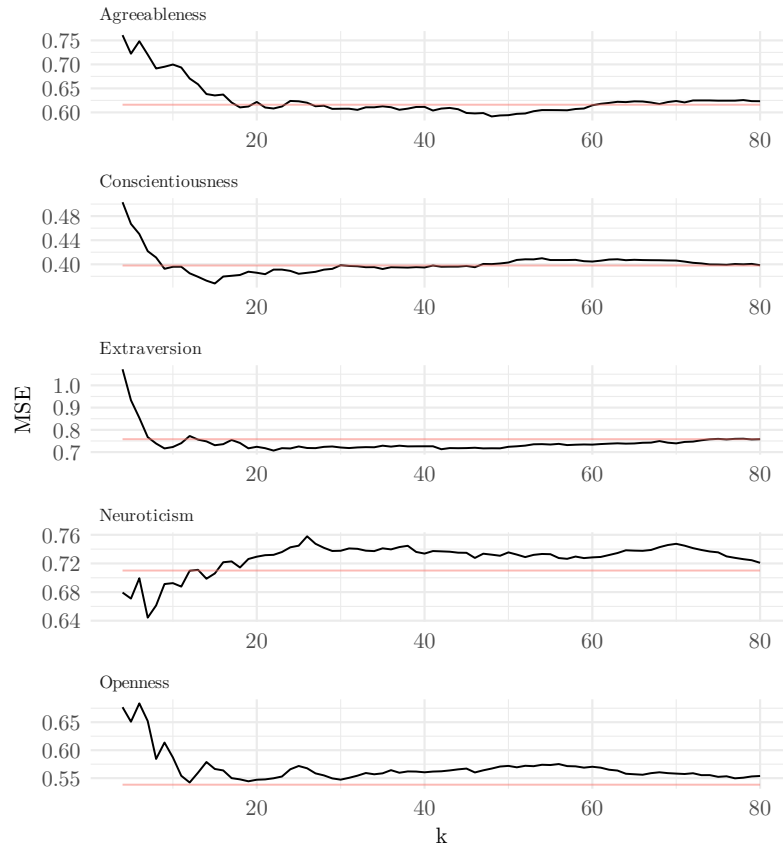

Figure 3.2: MSE by personality trait for base setup prediction.

improvement compared to the trivial prediction.

Given that the performance of the predictions is just slightly better than average in most cases, we contemplate other scenarios with different variations of the hyperparameters considered in this section, namely the cost matrix and choice of normalized distance.

## Section 4

# Additional scenarios considered for prediction

In order to find better prediction for the personality scores, we considered different configurations for the obtention of the cost matrix. For instance:

- Take the constant  $c$  in 1.1 as  $2 * \max_{1 \leq i, j \leq n} P(i, j)$  so that  $0 \leq K(s_i, s_j) \leq 2 * \max_{1 \leq i, j \leq n} P(i, j) \leq 2$ .
- Consider the methods **FUTURE**, **INDELS** and **INDELSLOG** for the calculation of the cost matrix.
- Try **gmean** and **maxdist** as the normalization factor for the distance matrix.
- Consider several values from 0 to 2 for the transition from/to missing value, given that this has a significant effect when comparing sequences with large differences in length. Also, we can appreciate this effect in the conformation of the clusters (see 2.2).
- Given that the previous consideration resulted in better prediction performance, and with the aim of obtaining more homogeneous sequences in length, we limit the start and end age of the sequences.

The following table shows some of the scenarios considered. With the purpose of comparing the predictions obtained with the different scenarios, we calculate the relative improvement ( $p$ ) compared to the trivial prediction for each value of  $k$  and each scenario.

$$p = (1 - (MSE_k / MSE_{trivial})) * 100 \quad (4.1)$$

Table 4.1: Summary of the additional scenarios considered

	Cost matrix	Normalization	Transition constant	NA cost	Min age	Max age
1	TRATE	maxlength	NULL	NULL	NULL	NULL
2	TRATE	maxlength	0.08021433	NULL	NULL	NULL
3	TRATE	gmean	0.08021433	NULL	NULL	NULL
4	FUTURE	maxlength	NULL	NULL	NULL	NULL
5	INDELS	maxlength	NULL	NULL	NULL	NULL
6	INDELSLOG	maxlength	NULL	NULL	NULL	NULL
7	FUTURE	gmean	NULL	NULL	NULL	NULL
8	FUTURE	maxdist	NULL	NULL	NULL	NULL
9	FUTURE	gmean	NULL	1	NULL	NULL
10	FUTURE	gmean	NULL	NULL	20	55
11	FUTURE	gmean	NULL	NULL	20	40
12	FUTURE	gmean	NULL	1	20	55
13	FUTURE	gmean	NULL	0.5	20	55

Figure 4.2 shows the best relative improvement achieved for each personality trait and under all the scenarios in 4.1 and the corresponding value of  $k$  at which the best performance was obtained. We can observe that there is not a single scenario that produces the best prediction improvement for every trait. Although, the method **FUTURE** seems to produce better results for all of the traits except neuroticism.

Figure 4.3 shows the MSE for neuroticism in scenario 2 in which the cost matrix is calculated with transition rates, the normalization method for the distances is **maxlength** and the constant  $c$  was modified. We can observe that the best prediction is achieved at  $k = 6$ . However, the MSE at this point is much lower than the rest of the curve. It might be the case that this is a random occurrence. However, in 4.2 we observe the minimum MSE is found with a similar number of neighbors for other scenarios, for instance, in scenario 3 (see Figure 4.4). For openness, the best predictions are obtained with scenarios 12 and 13. In both scenarios the cost matrix is calculated with  $\chi^2$  distance of the states frequencies (method **FUTURE**), normalization with the method **gmean** and the sequences are restricted between 20 and 55 years of age. This scenarios differ in the cost assigned to changes involving missing values. Hence, we might infer that the prediction of openness is highly affected by the way missing values are handled. Figure 4.5 shows the MSE for openness in scenario 13. In this case, we observe that the curve is lower around the values near to where the minimum is obtained at  $k = 13$  and it increases to values where the performance is worst than the trivial prediction from  $k > 25$ .

The scenario that produces the best prediction for extraversion is number 9. In Figure 4.6, the MSE for this scenario is shown. In this case, the minimum MSE is obtained when  $k = 18$  which is a high number of neighbors compared to the two

Figure 4.2: Relative MSE improvement in the prediction of personality traits.

previous traits. As expected, the MSE decreases until this value and then starts to increase again, a sign of overfitting for bigger values of  $k$ .

For conscientiousness none of the predictions achieved a relative improvement of at least 10%. Furthermore, the best prediction is obtained for  $k = 15$  in the base scenario. Scenario 12 produces a similar result in terms of improvement, but with  $k = 51$  which is an undesirable high number of neighbors for prediction with  $k$ NN. Figure 4.7 shows in detail the MSE for conscientiousness in the base scenario. Likewise, for agreeableness, all of the scenarios showed improvements relative to the trivial prediction that are below 10% and the minimum MSE in every case is obtained for rather large values of  $k$ . This could be an indication of poor predictive power of the relationships history of women for this particular trait. However, as expected for this prediction technique, we observe in Figure 4.8 that the MSE is large and even greater than the MSE of the trivial prediction for values of  $k$  below 25 and after achieving the minimum it starts increasing again. Finally, we perform clustering again with the distance matrix obtained in Scenario 13. Table 4.9 shows the cost matrix for this

Figure 4.3: MSE of neuroticism prediction in scenario 2.

setup of parameters. We can appreciate that in this case the range of the values of the cost matrix (excluding the diagonal elements and the missing value cost) is larger than those observe in 2.1. Figure 4.10 shows the distribution of states by cluster for this scenario. Even tough the cost matrix presented large variations compared to the base scenario and the predictions improved, we obtain clusters that exhibit similar main characteristics: In cluster 1, we find women with different relationship situations but without children. Similarly, in cluster 2 we find women with different relationship trajectories, but mostly married, that eventually had children. The clusters seem to be better defined in this case but that can be also due to the age restriction imposed, which implies that some sequences without enough data in the specified age range were excluded.

# Conclusion

The use of optimal matching to describe sequential data in the context of social studies has been extensively documented. We explored the potential to use this technique for prediction. Despite the lack of a measure to directly compare cost or distance matrices produced by optimal matching, we decided to use MSE to evaluate different scenarios as our main goal was to obtain good performance with the predictions.

Based on the analysis of the distance matrix obtained through optimal matching, we have determined that there is not a single specific combination of cost matrix generation method, normalization method, and treatment of missing values that consistently yields the best prediction for personality scores. However, when it comes to most personality traits, it is preferable to use the cost matrix calculated with the  $\chi^2$  distance of the states frequencies. It is worth noting that critics of this technique have pointed out that the results heavily rely on how the cost matrix is defined and we have confirmed this with our results.

We also noted that the difference in sequence lengths affected the performance of the prediction as this produced a large amount of missing values, showing the limitation of any normalization method used.

Furthermore, we also observed that in the two scenarios that we considered for clustering, the resulting states distributions when dividing the individuals into two clusters, show that the main differentiating factor between them is the presence or absence of children (see Figure 2.6 and Figure 4.10).

As for future work, we consider that it would be convenient to consider another method for obtaining the cost matrix. For instance, in the specific context of the relationship history, it makes sense to consider an asymmetrical cost matrix as it is likely that the change from one state to another is more frequent than the converse.
